0.1 "Testsuite" of examples

1. $\lambda(x : \text{Int}*\text{Int}).(\lambda(z : \text{Int}).z)\,x$: This example should not type-check because it leads to an ambiguous choice in the body of the lambda. In the current system the well-formedness checks forbid such example.

2. $\Lambda A.\Lambda B.\lambda(x : A).\lambda(y : B).(\lambda(z : A).z)(x,,y)$: This example should not type-check because it is not guaranteed that the instantiation of A and B produces a well-formed type. The TyMerge rule forbids it with the disjointness check.

$$\boxed{\Gamma \vdash A \bot B}$$

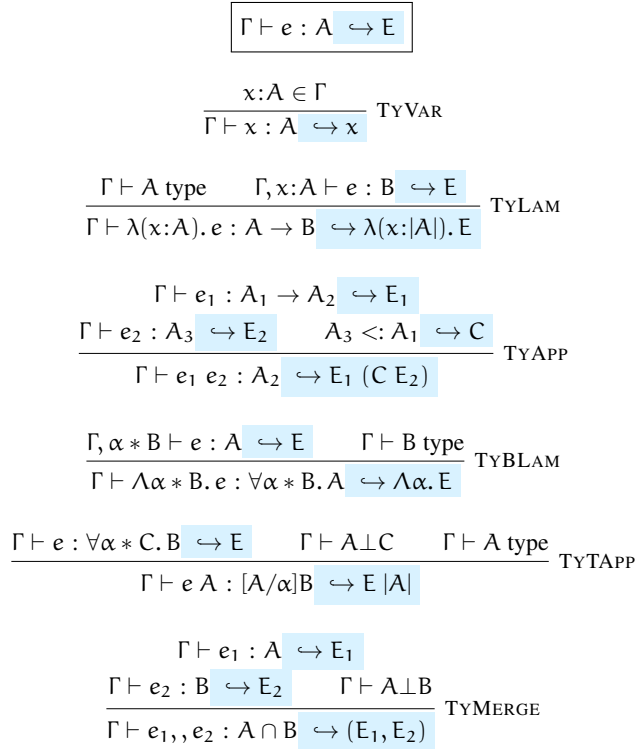

Figure 5. Typing.

3. $\Lambda A.\Lambda B * A.\lambda(x : A).\lambda(y : B).(\lambda(z : A).z)(x,, y)$: This example should type-check because B is guaranteed to be disjoint with A. Therefore instantiation should produce a well-formed type.

4. $(\lambda(z : Int).z)((1,,'c'),, (2, False))$: This example should not type-check, since it leads to an ambiguous lookup of integers (can either be 1 or 2). The definition of disjointness is crutial to prevent this example from type-checking. When type-checking the large merge, the disjointness predicate will detect that more than one integer exists in the merge.

5. $(\lambda(f : Int \to Int\&Bool).\lambda(g : Int \to Char\&Bool).((f,, g) : Int \to Bool)$: This example should not type-check, since it leads to an ambiguous lookup of functions. It shows that in order to check disjointness of functions we must also check disjointness of the subcomponents.

6. $(\lambda(f : Int \to Int).\lambda(g : Bool \to Int).((f,, g) : Bool\&Int \to Int)$: This example shows that whenever the return types overlap, so does the function type: we can always find a common subtype for the argument types.

0.2 Achieving Coherence

The crutial challenge lies in the generation of coercions, which can lead to different results due to multiple possible choices in the rules that can be used. In particular the rules SubAnd1 and SubAnd2 overlap and can result in coercions that are not equivalent. A simple example is:

$(\lambda(x : Int).x)(1,, 2)$

The result of this program can be either 1 or 2 depending on whether we chose SubAnd1 or SubAnd2.

Therefore the challenge of coherence lies in ensuring that, for any given types A and B, the result of A <: B always leads to the same (or semantically equivalent) coercions.

It is clear that, in general, the following does not hold:

if $A <: B \rightsquigarrow C1$ and $A <: B \rightsquigarrow C2$ then $C1 = C2$

We can see this with the example above. There are two possible coercions:

$(Int\&Int) <: Int \rightsquigarrow \lambda(x, y).x$
$(Int\&Int) <: Int \rightsquigarrow \lambda(x, y).y$

However $\lambda(x, y).x$ and $\lambda(x, y).y$ are not semantically equivalent.

One simple observation is that the use of the subtyping relation on the example uses an ill-formed type (Int&Int). Since the type system can prevent such bad uses of ill-formed types, it could be that if we only allow well-formed types then the uses of the subtyping relation do produce equivalent coercions. Therefore the we postulate the following conjecture:

if $A <: B \rightsquigarrow C1$ and $A <: B \rightsquigarrow C2$ and A, B well formed then $C1 = C2$

If the following conjecture does hold then it should be easy to prove that the translation is coherent.

$$\epsilon \vdash 1,, 2 : (Int * Int) \Rightarrow Int \cap Int$$

We say two types are *disjoint* if they do not share a common supertype.

Definition 1 (Disjointness). $A \bot B = \nexists C. A <: C \land B <: C$

1. Polymorphism with disjoint constraint

With a subtyping relation in a type system, bounded polymorphism extends the universal quantifier by confining the polymorphic type to be a subtype of a given type. In our type system, the forall binder also extends the parametric polymorphism, but in a different vein: the polymorphic type can only be disjoint with a given type.

- **Bounded polymorphism**—the instantiation can only be the descendant of a given type

- **Polymorphism with disjoint constraint**—the instantiation cannot share a common ancestor with a given type

The intuition can be found in figure . . . .

## 2. Proof

2.1 Sketch of the proof

Lemma 1 (Unique subtype contributor). *If* $A \cap B <: C$, *where* $A \cap B$ *and* C *are well-formed types, then one and only one of the following is possible:*

1. $A <: C$
2. $B <: C$

If $A \cap B <: C$, then either A or B contributes to that subtyping relation, but not both. The implication of this lemma is that during the derivation, it is not possible that two rules are applicable.

Proof. Idea: First we will show that the $A <: C$ and $B <: C$ cannot hold simultaneously. Then we will show that at least one of them holds.

For the first claim, since $A \cap B$ is well-formed, $A * B$. Then by the definition of disjointness, there does not exist a type C such that $A <: C$ and $B <: C$. It follows that $A <: C$ and $B <: C$ cannot hold simultaneously.

2 2 2

C_2 — C_2 — C_2

{1}
Figure 6. Untergruppenverband

For the second claim, let's suppose the contrary. Then it is impossible that $A \cap B <: C$. □

The coercion of a subtyping relation $A <: B$ is uniquely determined.

Lemma 2 (Unique coercion). *If* $A <: B \hookrightarrow C_1$ *and* $A <: B \hookrightarrow C_2$ *, where* A *and* B *are well-formed types, then* $C_1 \equiv C_2$

Proof. By 1. □

Lemma 3. *If* $\Gamma \vdash e : \tau \hookrightarrow E$ *, then* τ *is a well-formed type.*

Given a source expression e, elaboration always produces the same target expression E.

Theorem 1 (Unique elaboration). *If* $\Gamma \vdash e : \tau_1 \hookrightarrow E_1$ *and* $\Gamma \vdash e : \tau_2 \hookrightarrow E_2$ *, then* $E_1 \equiv E_2$
